Multiple linear regression

Grading the professor

Many college courses conclude by giving students the opportunity to evaluate the course and the instructor anonymously. However, the use of these student evaluations as an indicator of course quality and teaching effectiveness is often criticized because these measures may reflect the influence of non-teaching related characteristics, such as the physical appearance of the instructor. The article titled, "Beauty in the classroom: instructors' pulchritude and putative pedagogical productivity" (Hamermesh and Parker, 2005) found that instructors who are viewed to be better looking receive higher instructional ratings. (Daniel S. Hamermesh, Amy Parker, Beauty in the classroom: instructors pulchritude and putative pedagogical productivity, *Economics of Education Review*, Volume 24, Issue 4, August 2005, Pages 369-376, ISSN 0272-7757, 10.1016/j.econedurev.2004.07.013. http://www.sciencedirect.com/science/article/pii/S0272775704001165.)

In this lab we will analyze the data from this study in order to learn what goes into a positive professor evaluation.

The data

The data were gathered from end of semester student evaluations for a large sample of professors from the University of Texas at Austin. In addition, six students rated the professors' physical appearance. (This is a slightly modified version of the original data set that was released as part of the replication data for *Data Analysis Using Regression and Multilevel/Hierarchical Models* (Gelman and Hill, 2007).) The result is a data frame where each row contains a different course and columns represent variables about the courses and professors.

Exploring the data

1. Is this an observational study or an experiment? The original research question posed in the paper is whether beauty leads directly to the differences in course evaluations. Given the study design, is it possible to answer this question as it is phrased? If not, rephrase the question.

Exercise 1 Answer:

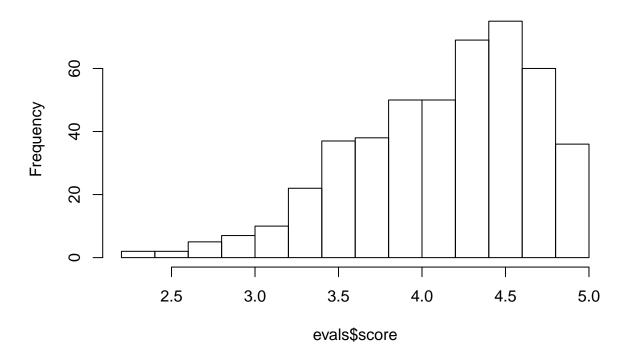

This is an observational study. As such, we can't really determine causation, so I don't like the 'leads directly' wording. I would change it to 'is there a relationship between beauty ratings and course evaluations?'.

2. Describe the distribution of score. Is the distribution skewed? What does that tell you about how students rate courses? Is this what you expected to see? Why, or why not?

Exercise 2 Answer:

hist(evals\$score)

Histogram of evals\$score

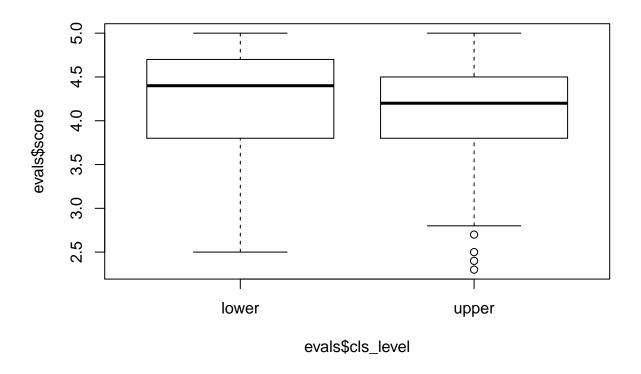

The distribution of score is skewed to the left. It looks like students usually rate courses positively. This is, in fact, exactly what I expected. A lot of classes are positive experiences and even when they aren't, I think students will be predisposed towards not making negative statements even if the responses are truly anonymous.

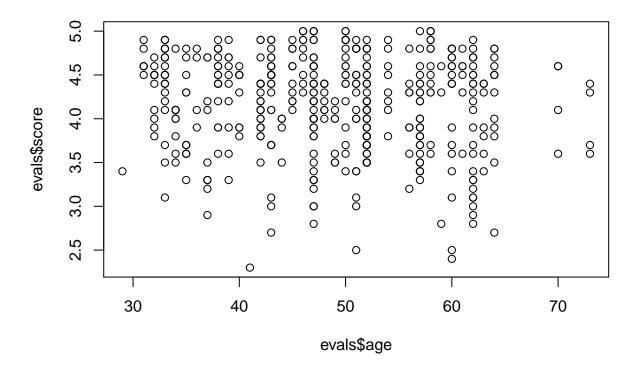

3. Excluding score, select two other variables and describe their relationship using an appropriate visualization (scatterplot, side-by-side boxplots, or mosaic plot).

Exercise 3 Answer:

```
# Boxplots of class level vs score
plot(evals$score ~ evals$cls_level)
```

```
# Scatterplot of age of professor vs score
plot(x = evals$age, y = evals$score)
```

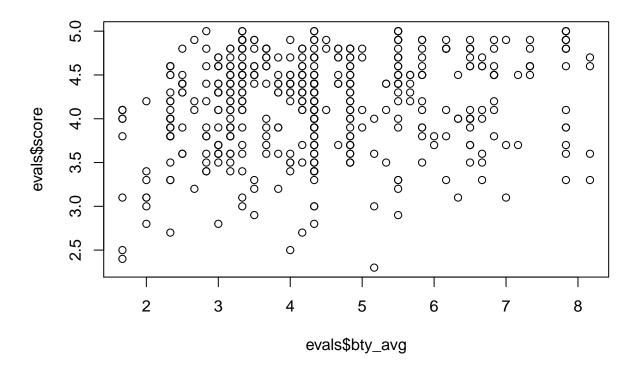

The class level appears to possibly affect teacher ratings. Upper class students are more critical on the whole than lower class students. There scatterplot between age of professor and rating does not seem to indicate any kind of relationship.

Simple linear regression

The fundamental phenomenon suggested by the study is that better looking teachers are evaluated more favorably. Let's create a scatterplot to see if this appears to be the case:

plot(evals\$score ~ evals\$bty_avg)

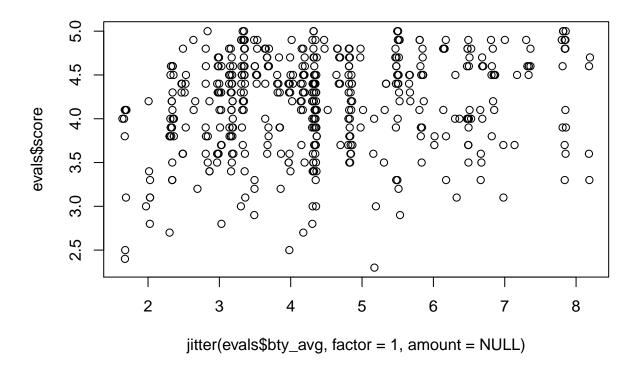

Before we draw conclusions about the trend, compare the number of observations in the data frame with the approximate number of points on the scatterplot. Is anything awry?

4. Replot the scatterplot, but this time use the function jitter() on the y- or the x-coordinate. (Use ?jitter to learn more.) What was misleading about the initial scatterplot?

Exercise 4 Answer:

```
plot(evals$score ~ jitter(evals$bty_avg, factor = 1, amount = NULL))
```

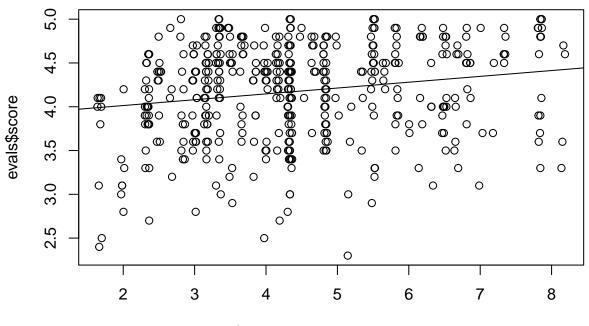

Many of the points on the scatterplot were actually multiple points which looked like one point because they were all in the exact same spot. Adding the jitter makes it clear that many points are multiple plots.

5. Let's see if the apparent trend in the plot is something more than natural variation. Fit a linear model called m_bty to predict average professor score by average beauty rating and add the line to your plot using abline(m_bty). Write out the equation for the linear model and interpret the slope. Is average beauty score a statistically significant predictor? Does it appear to be a practically significant predictor?

Exercise 5 Answer:

```
# fit linear regression model
m_bty <- lm(score ~ bty_avg, data = evals)
# create scatterplot again
plot(evals$score ~ jitter(evals$bty_avg, factor = 1, amount = NULL))
# add line on top of scatterplot
abline(m_bty)</pre>
```

jitter(evals\$bty_avg, factor = 1, amount = NULL)

summary(m_bty)

```

## Residual standard error: 0.5348 on 461 degrees of freedom
## Multiple R-squared: 0.03502,
                                    Adjusted R-squared: 0.03293
## F-statistic: 16.73 on 1 and 461 DF, p-value: 5.083e-05
```

Equation for linear model: $score = 3.88034 + 0.06664 * bty_avg$

The slope means that each increment of 1 in the bty_avg is associated with an increase of 0.06664 in the score.

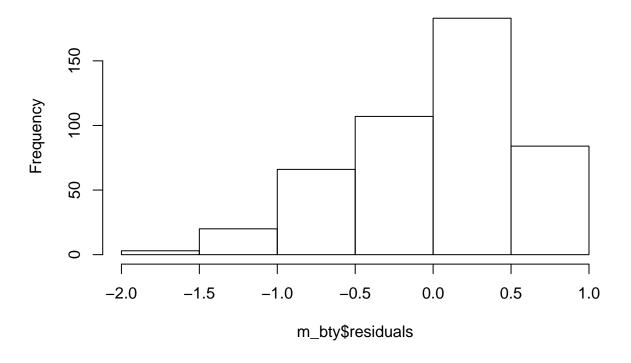

Given the extremely low p-value, it does appear the average beauty score is a statistically significant indicator. Given the range of values for bty_avg from 1.667 to 8.167, and the fact that the slope is only 0.06664, the range of effect for the bty_avg on the score is going to be 1.667 * 0.06664 to 8.167 * 0.06664, or 0.111 to 0.544. This is not necessarily a huge effect on a score that ranges between 1 and 5.

6. Use residual plots to evaluate whether the conditions of least squares regression are reasonable. Provide plots and comments for each one (see the Simple Regression Lab for a reminder of how to make these).

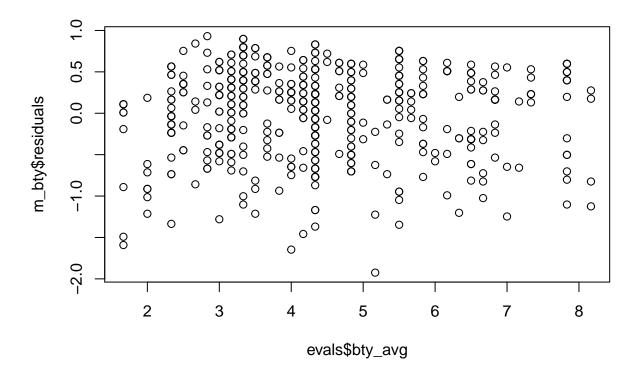

Exercise 6 Answer:

```
# nearly normal residuals? (some left skew)
hist(m_bty$residuals)
```

Histogram of m_bty\$residuals

```
# constant variability? (looks pretty good)
plot(m_bty$residuals ~ evals$bty_avg)
```

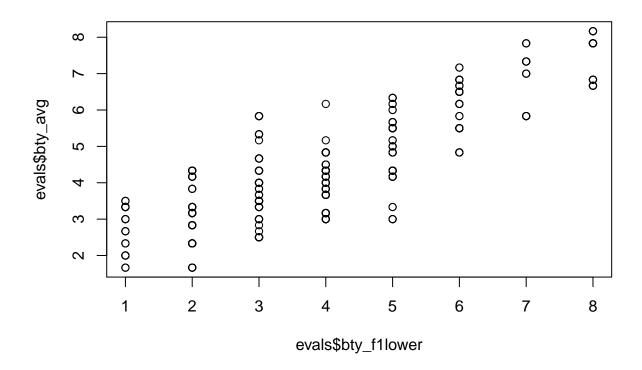

as far as linearity, see scatterplot from Exercise 4

Multiple linear regression

The data set contains several variables on the beauty score of the professor: individual ratings from each of the six students who were asked to score the physical appearance of the professors and the average of these six scores. Let's take a look at the relationship between one of these scores and the average beauty score.

plot(evals\$bty_avg ~ evals\$bty_f1lower)

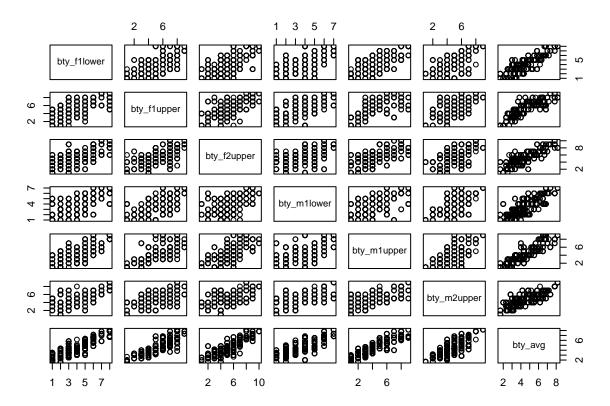

cor(evals\$bty_avg, evals\$bty_f1lower)

[1] 0.8439112

As expected the relationship is quite strong - after all, the average score is calculated using the individual scores. We can actually take a look at the relationships between all beauty variables (columns 13 through 19) using the following command:

plot(evals[,13:19])

These variables are collinear (correlated), and adding more than one of these variables to the model would not add much value to the model. In this application and with these highly-correlated predictors, it is reasonable to use the average beauty score as the single representative of these variables.

In order to see if beauty is still a significant predictor of professor score after we've accounted for the gender of the professor, we can add the gender term into the model.

```
m_bty_gen <- lm(score ~ bty_avg + gender, data = evals)
summary(m_bty_gen)</pre>
```

```
##

```

7. P-values and parameter estimates should only be trusted if the conditions for the regression are reasonable. Verify that the conditions for this model are reasonable using diagnostic plots.

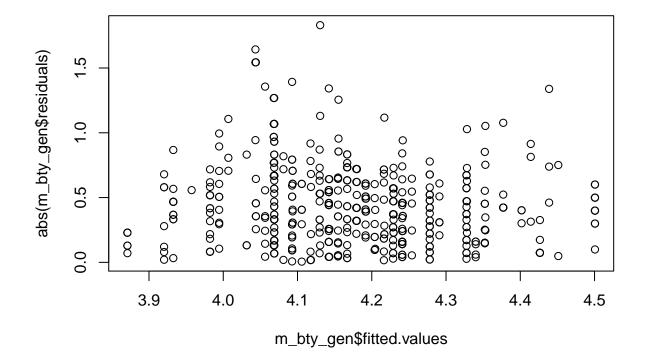

Exercise 7 Answer:

```
# the residuals of the model are nearly normal
qqnorm(m_bty_gen$residuals)
qqline(m_bty_gen$residuals)
```

Normal Q-Q Plot

```
# the variability of the residuals is nearly constant
# fitted values vs absolute value of residuals
plot(x = m_bty_gen$fitted.values, y = abs(m_bty_gen$residuals))
```

8. Is bty_avg still a significant predictor of score? Has the addition of gender to the model changed the parameter estimate for bty_avg?

Exercise 8 Answer:

Yes, it is still a significat predictor for score. The addition of gender to the model has changed the parameter estimate from 0.06664 to 0.07416

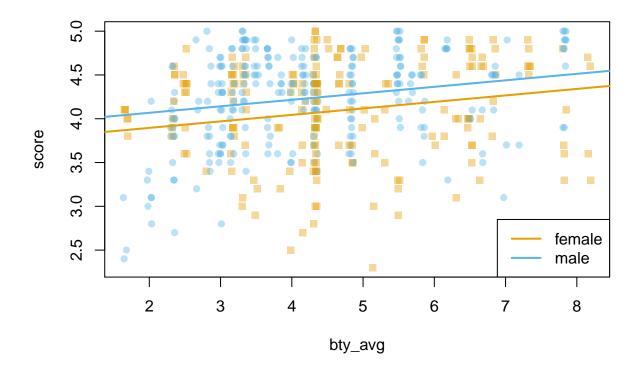

Note that the estimate for gender is now called gendermale. You'll see this name change whenever you introduce a categorical variable. The reason is that R recodes gender from having the values of female and male to being an indicator variable called gendermale that takes a value of 0 for females and a value of 1 for males. (Such variables are often referred to as "dummy" variables.)

As a result, for females, the parameter estimate is multiplied by zero, leaving the intercept and slope form familiar from simple regression.

$$\widehat{score} = \hat{\beta}_0 + \hat{\beta}_1 \times bty_avg + \hat{\beta}_2 \times (0)$$
$$= \hat{\beta}_0 + \hat{\beta}_1 \times bty \quad avg$$

We can plot this line and the line corresponding to males with the following custom function.

multiLines(m_bty_gen)

9. What is the equation of the line corresponding to males? (*Hint:* For males, the parameter estimate is multiplied by 1.) For two professors who received the same beauty rating, which gender tends to have the higher course evaluation score?

Exercise 9 Answer:

The equation for males is: $score = 3.74734 + 0.07416 * bty_avg + 0.17239$, or $score = 3.91973 + 0.07416 * bty_avg$

The decision to call the indicator variable gendermale instead ofgenderfemale has no deeper meaning. R simply codes the category that comes first alphabetically as a 0. (You can change the reference level of a categorical variable, which is the level that is coded as a 0, using therelevel function. Use ?relevel to learn more.)

10. Create a new model called m_bty_rank with gender removed and rank added in. How does R appear to handle categorical variables that have more than two levels? Note that the rank variable has three levels: teaching, tenure track, tenured.

Exercise 10 Answer:

```
m_bty_rank <- lm(score ~ bty_avg + rank, data = evals)
summary(m_bty_rank)</pre>
```

Call:

```
## lm(formula = score ~ bty_avg + rank, data = evals)
##
## Residuals:
##

```

Appears to again be alphabetical. teaching is set to 0, tenure track is 1, and tenured is 2.

The interpretation of the coefficients in multiple regression is slightly different from that of simple regression. The estimate for bty_avg reflects how much higher a group of professors is expected to score if they have a beauty rating that is one point higher while holding all other variables constant. In this case, that translates into considering only professors of the same rank with bty_avg scores that are one point apart.

The search for the best model

We will start with a full model that predicts professor score based on rank, ethnicity, gender, language of the university where they got their degree, age, proportion of students that filled out evaluations, class size, course level, number of professors, number of credits, average beauty rating, outfit, and picture color.

11. Which variable would you expect to have the highest p-value in this model? Why? *Hint:* Think about which variable would you expect to not have any association with the professor score.

Exercise 11 Answer:

I'll say number of professors because that would not seem to matter.

Let's run the model...

```
##

12. Check your suspicions from the previous exercise. Include the model output in your response.

Exercise 12 Answer:

Number of professors had a highest p-value (see exercise 11 output, value is 0.77806)

lm(formula = score ~ rank + ethnicity + gender + language + age +

13. Interpret the coefficient associated with the ethnicity variable.

Exercise 13 Answer:

If the professor is not a minority, their score will be 0.1234929 higher, holding all other variables constant.

14. Drop the variable with the highest p-value and re-fit the model. Did the coefficients and significance of the other explanatory variables change? (One of the things that makes multiple regression interesting is that coefficient estimates depend on the other variables that are included in the model.) If not, what does this say about whether or not the dropped variable was collinear with the other explanatory variables?

Exercise 14 Answer:

Call:

```
m_wo_cls_profs <- lm(score ~ rank + ethnicity + gender + language + age + cls_perc_eval + cls_students
summary(m_wo_cls_profs)
##</pre>
```

```
##

## F-statistic: 7.943 on 13 and 449 DF, p-value: 2.336e-14
```

The coefficients and significance of the other explanatory variables did change, but by very minor amounts. The amount of change was small enough to conclude there was a lot of collinearity between the dropped variable and the other explanatory variables.

15. Using backward-selection and p-value as the selection criterion, determine the best model. You do not need to show all steps in your answer, just the output for the final model. Also, write out the linear model for predicting score based on the final model you settle on.

Exercise 15 Answer:

The best model using backward-selection and p-value is the same model shown in Exercise 14. The linear model is as shown below:

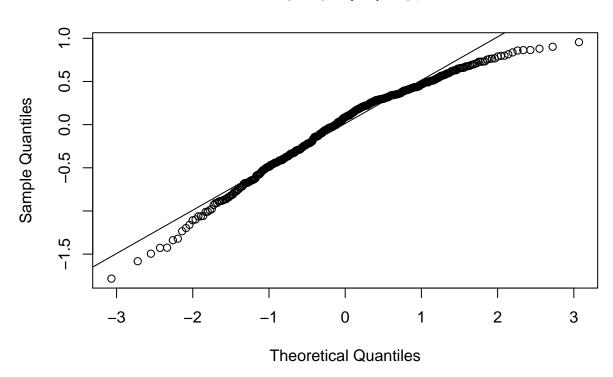

```
score = 4.0872523 - 0.1476746 * ranktenure\_track - 0.0973829 * ranktenured + 0.1274458 * ethnicity + 0.2101231 * gender - 0.2282894 * language - 0.0089992 * age + 0.0052888 * cls\_perc\_eval + 0.0004687 * cls\_students + 0.0606374 * cls\_levelupper + 0.5061196 * cls\_credits + 0.0398629 * bty\_avg - 0.1083227 * pic\_outfit - 0.2190527 * pic\_color
```

16. Verify that the conditions for this model are reasonable using diagnostic plots.

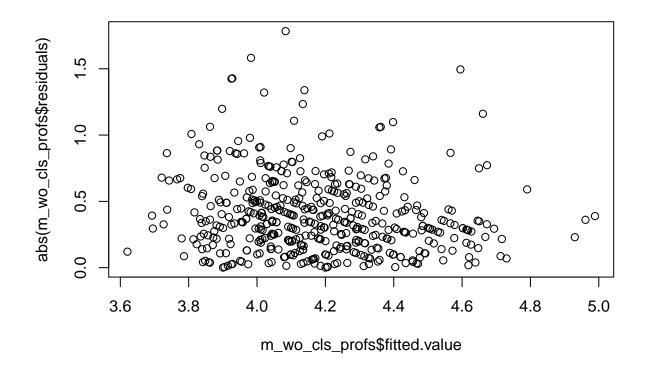

Exercise 16 Answer:

```
# normal probability plot of residuals
qqnorm(m_wo_cls_profs$residuals)
qqline(m_wo_cls_profs$residuals)
```

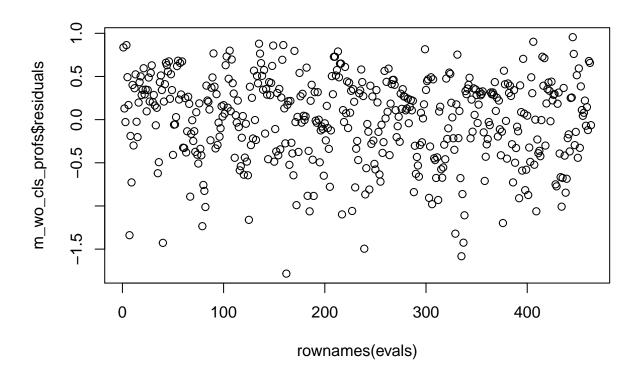

Normal Q-Q Plot

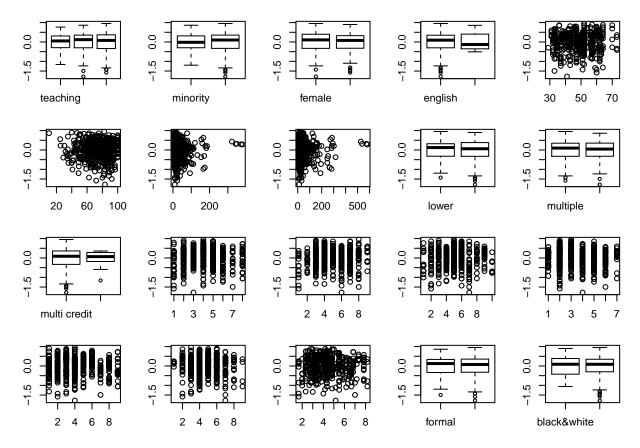

```
# fitted values vs residuals
plot(x = m_wo_cls_profs$fitted.value, y = abs(m_wo_cls_profs$residuals))
```

```
# residuals in order of data collection
plot(x = rownames(evals), y = m_wo_cls_profs$residuals)
```

```
# residuals against each predictor variable
resid_plots <- function(i) {
  for (i in 2:21) {
    plot(x = evals[,i], y = m_wo_cls_profs$residuals)
  }
}
par(mfrow=c(4,5))
par(mar = rep(2, 4))
resid_plots()</pre>
```

17. The original paper describes how these data were gathered by taking a sample of professors from the University of Texas at Austin and including all courses that they have taught. Considering that each row represents a course, could this new information have an impact on any of the conditions of linear regression?

Exercise 17 Answer:

I would question whether the observations are independent, because having the same professor repeatedly could affect ratings and calls into question the 'residuals in order of data collection' condition.

18. Based on your final model, describe the characteristics of a professor and course at University of Texas at Austin that would be associated with a high evaluation score.

Exercise 18 Answer:

They would not be a minority, they would be male, the student would be an upper level student in a 1-credit course and the teacher would have a good bty_avg.

19. Would you be comfortable generalizing your conclusions to apply to professors generally (at any university)? Why or why not?

Exercise 19 Answer:

I would not be comfortable generalizing to any university, because universities can vary considerably, as do the student bodies and different universities.
